**Abstract:** The practical use of aqueous zinc ion batteries (AZIBs) has been greatly limited for a long time because zinc anode dendrites grow and parasitic reactions occur. This study synergistically controls the zinc deposition behavior by adding two additives, sodium lignin sulfonate(SLS) and sodium gluconate (SG), to ZnSO<sub>4</sub> electrolyte. The results showed that SLS prefers to adsorb on the metallic zinc surface, which can form a three-dimensional molecular network, guiding the zinc nucleation and growth and also repel water molecules nearby. Creating a dried out electric double layer at the 0metal/electrolyte interface. At the same time, SG is participating in the primary solvation shell of Zn<sup>2+</sup> and displaces very reactive water molecules to suppress hydrogen evolution and self-corrosion, refine zinc grain size and promote uniform deposition. Taking advantage of this two additions strategy, the Zn||ZS+SLG symmetrical cell can obtain a long cycle life of 2000 h at 1 mA cm<sup>-2</sup> and 1 mAh cm<sup>-2</sup>, and the lifespan of the cell is greatly improved at higher current density and higher areal capacity. In addition, under more realistic conditions, the Zn||MnO<sub>2</sub>@CNT whole cell retained a capacity of about 300 mAh g<sup>-1</sup> after 600 cycles at 2 A g<sup>-1</sup>. The results show that this simple electrolyte regulation strategy greatly improves the stability of the zinc anode interface, which can provide a practical approach to construct economically competitive and engineering feasible aqueous energy storage systems, and also promotes the commercialization of AZIBs.

## 4 **1. Introduction**

7 With the dual increase in high penetration of renewable energy and the demand  
8 for flexible grids, it is becoming a "hard constraint" for safe, sustainable and  
9 affordable energy storage technologies to be an "alternative" technology to ensure the  
10 stable operation of energy systems<sup>[1-4]</sup>. Lithium-ion batteries allowed a leapfrogging  
11 of mobile electronics and electric vehicles in the last 20 years because they have high  
12 energy densities and well-developed manufacturing processes. However, the fact that  
13 lithium-ion batteries suffer from uneven endowments of important resources, cost  
14 sensitivities, and safety/environmental trade-offs with organic electrolytes impose  
15 practical barriers to grid-scale applications that require long lifetimes, extended  
16 periods of operation, and large sizes<sup>[5-11]</sup>. In contrast, aqueous zinc-ion batteries  
17 (AZIBs) become a promising candidate for the new power supply system and  
18 distributed energy storage because of its abundant raw material, large theoretical  
19 capacity, inherent safety of aqueous electrolytes, low-cost materials. But engineering  
20 and scaling require surmounting a series of "hard" interface and window-related  
21 challenges<sup>[12-23]</sup>. Including cathode dissolution and structural degradation, zinc anode  
22 dendrite formation, and self-corrosion, leading to a decrease in coulombic efficiency  
23 due to hydrogen evolution and side reactions, as well as a high temperature  
24 dependency for stability. Also, limitations exist in the conductivity and  
25 electrochemical stability window of traditional electrolytes<sup>[24-29]</sup>. In essence, it is due  
26 to the mismatch of solvation structures, electric double layer structures, interfacial  
27 reaction paths, and deposition morphologies under multiphysics of coupled  
28 thermodynamics-kinetics-mass transfer<sup>[30-32]</sup>.

31 Addressing the bottlenecks, in recent years, multidimensional synergistic  
32 strategies of materials, structures, and electrolyte engineering have emerged and  
33 achieved some crucial advances. And on the separator/mass transfer side, Sainan Ou  
34 added viscose fibers with irregular cross sections to the separator. With the groove

1 geometry and zinc-affinity polar groups on the fiber surface, it could promote  $Zn^{2+}$   
2 desolvation and directional migration<sup>[33]</sup>. Rate capability and cycling consistence was  
3 simultaneously improved. Yanpeng Guo did some work on the anode/morphology side,  
4 where he made zinc anodes under big electric currents to get more of the good kind of  
5 flat spots called (002) crystal planes, and to make a nice, even place for new bits of  
6 metal to stick to when they're forming<sup>[34]</sup>. This greatly expanded the window of  
7 operable current and reduced dendrite growth. On the electrolyte/interface side, Juan  
8 Zeng et al. reshaped the primary solvation shell of  $Zn^{2+}$  and constructed a dehydrated  
9 EDL using a "cation-affinity-enhanced" proline addition method, greatly stabilizing  
10 the anode interface<sup>[14]</sup>. Wang Pengtao Induce solvation and Helmholtz layer  
11 rearrangement via organic anionic surfactants (dodecylbenzenesulfonate), to form a  
12 dense organic-inorganic hybrid SEI in-situ, to suppress side-reactions and enhance  
13 long-cycle reversibility<sup>[35]</sup>. The sub-dodecahydro-anionic (SDA) strategy of Ruihao  
14 Luo group can separately manipulate the inner/outer Helmholtz plane and EDL  
15 structure<sup>[36]</sup>. A compromise of kinetic acceleration and side-reaction suppression is  
16 achieved by this way . These studies reveal effective pathways for stabilizing zinc  
17 anodes across four levels: "desolvation-crystal plane orientation-EDL  
18 reconstruction-artificial interface"-laying a solid foundation for extending the  
19 operational window under demanding conditions such as high areal loading, high  
20 current density, and low-concentration electrolytes.

42 However, from the perspectives of engineering feasibility and cross-scenario  
43 generalization, existing solutions still have some common limitations, including  
44 relatively limited functionality, being sensitive to the environment/process conditions,  
45 and being severely restricted in terms of costs and sustainability. For example,  
46 structured separators and engineered interfaces often depend on precise  
47 manufacturing and strict assembly for their performance advantage; certain ionic  
48 liquids or specialty solvents can have practical limitations regarding economic and  
49 environmental impact; more importantly, the coupling of these mechanisms along the  
50 whole chain : "additive-solvation-EDL-SEI- deposition morphology" - remains unclear.  
51 This prevents the strategy selection and parameter optimization from being transferred

1 to other operational conditions. Against this backdrop, Whether a multifunctional  
2 composite additive-green, low-cost, and compatible with existing manufacturing  
3 systems-can be developed to synergistically regulate the solvation structure, electric  
4 double-layer configuration, interfacial reactions, and deposition morphology without  
5 increasing manufacturing complexity has become a critical question; whether this  
6 strategy can offer a “gentle yet effective” solution to multi-objective coupled  
7 instabilities has also become an urgent issue.

8  
9  
10 To address this question, we explore the multi-target regulation potential of a  
11 composite additive system composed of gluconic acid and sodium lignin sulfonate  
12 in aqueous zinc-ion batteries. Gluconic acid (and its gluconate ion), as a highly polar,  
13 polyhydroxy ligand, competes with  $Zn^{2+}$  for water molecules in the primary solvation  
14 layer. This reduces free water activity and rearranges the local solvation sphere,  
15 thereby elevating the hydrogen evolution overpotential at the anode, suppressing  
16 self-corrosion and side reactions<sup>[37]</sup>. sodium lignin sulfonate , a widely available,  
17 low-cost, and environmentally friendly natural three-dimensional aromatic polymer,  
18 often decomposes into smaller molecular weight monomers under electric fields<sup>[38]</sup>.  
19 Its zinc-affinity groups, such as sulfonate and hydroxyl, enable selective adsorption  
20 onto metallic zinc surfaces, forming a flexible and adaptively rearranging organic  
21 interfacial layer. This layer homogenizes the electric field and ion flux, reduces  
22 nucleation barriers, and suppresses hotspot amplification and dendrite propagation. A  
23 synergistic division of labor exists between the two: gluconate ions primarily govern  
24 "under-hydration" at the solvation/EDL level and reaction pathway rearrangement,  
25 while sodium lignin sulfonate dominates "soft buffering" at the interface/morphology  
26 level and uniform deposition. So as to achieve a synergistic optimal solution for all of  
27 the solvation-EDL-SEI-morphology chain without involving high-cost solvents or  
28 complicated steps.The composite additive system stabilizes the zinc anode interface at  
29 optimal ratios, enabling Zn||Zn symmetric cells to cycle over 2000 hours with low  
30 polarization, achieving performance improvement through multi-process synergistic  
31 regulation; it is green and scalable, compatible with existing production lines, expands  
32 the operating window, and combines academic innovation with engineering practical

value.

## 2. Results and Discussion

Analyzing the van der Waals and electrostatic potential distribution for SLS and SG molecules (Fig. 1a), we can find there are some regions near polyhydroxy and sulfonate functional groups that the electrostatic potentials for SLS and SG are much less than that of water molecules. That means that compared with neutral water molecules, hydroxyl/sulfonate groups on SLS and SG have a stronger electrostatic attraction and coordination ability toward  $Zn^{2+}$ , which makes them more likely to establish stable interactions with  $Zn^{2+}$  in solutions. Thus, they competitively interact with the original hydration structure and capture  $Zn^{2+}$  from the electrolyte. Therefore, we systematically studied how changes in the additive concentration would affect the zinc deposit. Experiments show that at a concentration of 0.25 and 0.5 g/L of SLS and 0.125 and 0.25 M of SG, there is no improvement in the electrode polarization effect, voltage plateau, and cycling stability. It is clear that the solvent structure and the interfaces are not sufficiently remodeled at such additive levels. However, at SLS 2g/L and SG 1M, electrolyte became turbid and separated from solution when filling into the battery cell, which is a sign of poor solubility and processability. Taking both the balance of interface adjustment effects and homogeneity of the system into consideration, we chose SLS at a concentration of 1g/L and SG at a concentration of

1 0.5M for the concentration used in subsequent studies.

2 Under these conditions, we carried out the infrared and Raman characterization of  
3 electrolytes with different SLG content. As shown in Fig. 1b, the overall blue shift of  
4 the O-H stretching vibration peak in the 3200-3400  $\text{cm}^{-1}$  range with increasing SLG  
5 addition is a typical characteristic of weakened strong hydrogen bonds in water. This  
6 indicates that the dense network originally formed by water-water hydrogen bonds  
7 has been partially disrupted, with an increase in the proportion of free water and  
8 weakly hydrogen-bonded water. This finding strongly aligns with the hypothesis that  
9 SLG (the sulfonate group of SLS + the polyhydroxy/carboxylate group of SG)  
10 competitively "occupies" water molecules, altering their local environment. At the  
11 same time, the bending vibration peak of water molecules around 1640  $\text{cm}^{-1}$  shows a  
12 distinct redshift and a small degree of distortion, indicating that water molecules are  
13 no longer mainly involved in water-water hydrogen bonds. Instead, they interact more  
14 through coordination or direction hydrogen bonding with sulfonate/carboxylate  
15 groups, indirectly suggesting that the additive is participating in building up the  $\text{Zn}^{2+}$   
16 solvation shell. A small blue shift of the characteristic peak around 1080  $\text{cm}^{-1}$  can be  
17 ascribed to a higher priority for the Zn-SG complex formation and partial  
18 displacement of the  $\text{SO}_4^{2-}$  from the first solvation shell. It leads to the gradual  
19 transformation of the local structure from " $\text{Zn}^{2+}-(\text{H}_2\text{O})_n-\text{SO}_4^{2-}$ " to " $\text{Zn}^{2+}-\text{SG}-(\text{H}_2\text{O})_m$ ".

20 Further Raman testing (Fig. 1c) was conducted on ZS, ZS+0.5SLG, ZS+1SLG,  
21 and ZS+2SLG. As the SLG content increased, the spectral bands for strong hydrogen  
22 bonds gradually weakened, whereas the bands for medium and weak hydrogen bonds  
23 relatively strengthened. This shows a stepwise drop in strongly held water of high  
24 order inside the system, with more water becoming less tightly bound by organic  
25 groups-i.e., a pronounced overall drop in the proportion of "active free water". This  
26 change from a tight net of hydrogen bonds to one mainly made up of medium and  
27 weak ones helps stop the release of hydrogen and other chemical reactions closely  
28 related to intensely hydrated water, setting the stage for making a steady Zn edge  
29 atmosphere.

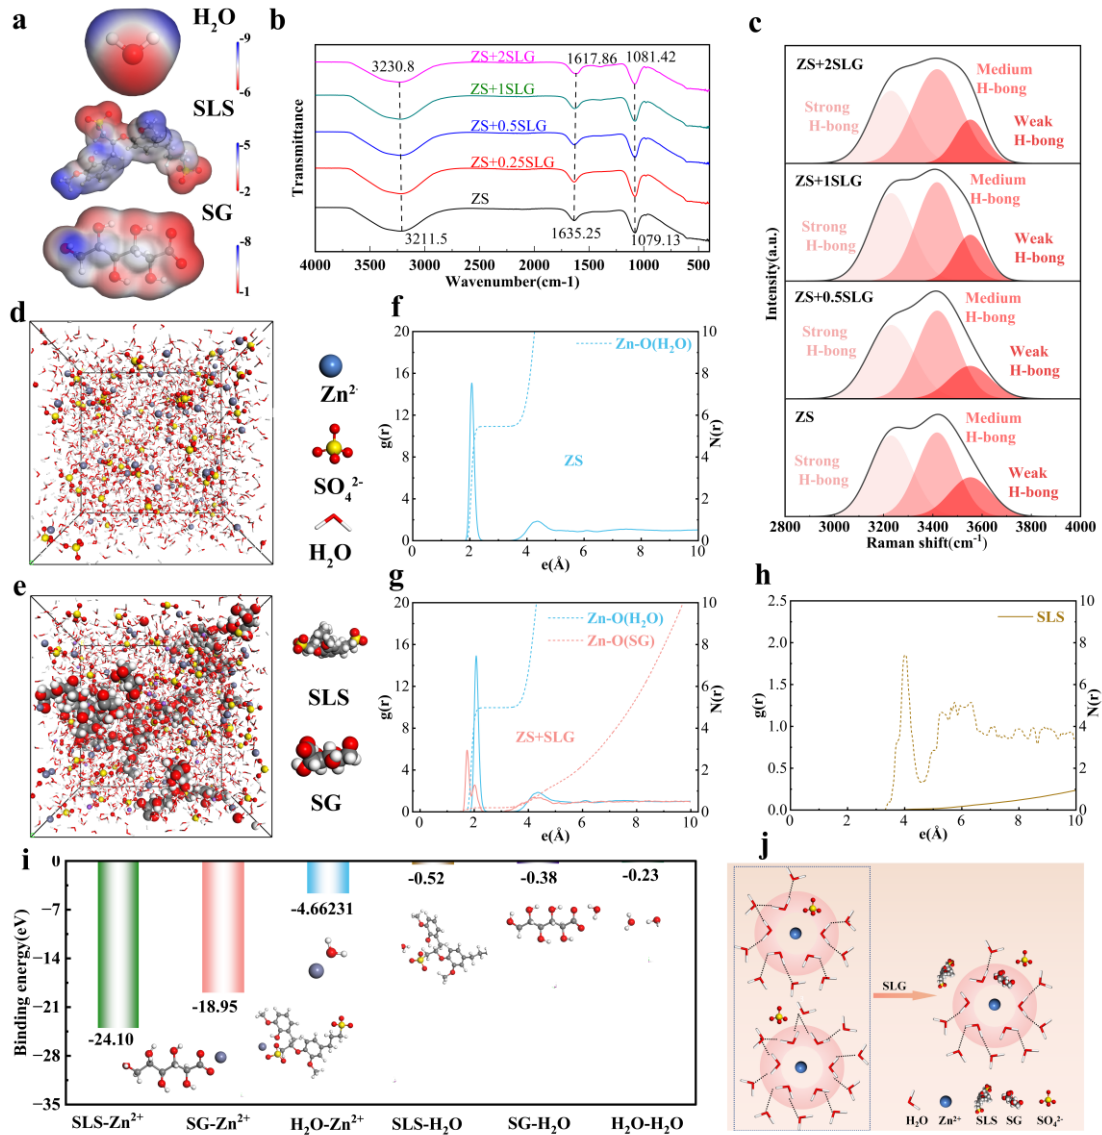

30 In order to explore how SLS/SG regulates the solvation structure at a molecular

1 level, we also performed molecular dynamics simulation(Fig. 1d, 1e). Radial  
2 distribution function and coordination number of the ZnSO<sub>4</sub> electrolyte without  
3 additives, as shown in Fig. 1f, show that Zn<sup>2+</sup>-O(H<sub>2</sub>O) has a distinct first coordination  
4 peak around 2.075 Å, corresponding to a water coordination number (CN) ≈ 5.64,  
5 indicating a primary solvation shell consisting mainly of water molecules. After  
6 introducing SLG, the CN of Zn<sup>2+</sup>-O(H<sub>2</sub>O) becomes around 4.98, which means there  
7 are some water molecules replaced by the functional groups of the additive.  
8 Concurrently, new coordination peaks emerge at 1.725 Å and 2.025 Å (Fig. 1g),  
9 primarily originating from multiple hydroxyl/carboxyl groups on the SG molecule  
10 coordinating to Zn<sup>2+</sup> via multipoint coordination with a coordination number of  
11 approximately 0.2. This clearly demonstrates SG's direct involvement in constructing  
12 the first solvation shell around Zn<sup>2+</sup>. In contrast, the larger SLS molecule exhibits only  
13 an extremely weak coordination signal at approximately 4 Å due to steric hindrance,  
14 with CN values approaching zero (Fig. 1h). This indicates that SLS barely enters the  
15 first solvation layer but instead tends to enrich near the electrode surface. There, it  
16 modulates the interfacial microenvironment through surface adsorption and the  
17 formation of three-dimensional molecular networks. Furthermore, to investigate the  
18 interactions between particles in the system, we calculated the adsorption energies  
19 between particles and between particles and the zinc electrode(Fig. 1g). We found that  
20 the adsorption energy of SG and SLS for Zn<sup>2+</sup> was 18.9eV and 24.1 eV, respectively,  
21 significantly higher than the adsorption energy of water for Zn<sup>2+</sup> (4.6 eV). This  
22 facilitates the participation of additive components in the formation of Zn<sup>2+</sup> solvation  
23 structures(Fig. 1i).

24 To experimentally verify the structural characteristics and component distribution  
25 of the three-dimensional molecular network formed by SLG on the zinc electrode  
26 surface, we performed XPS depth profiling on cycled zinc anodes (Fig. 2a, Fig. 2b,  
27 Fig. 2c and Fig S1). In the S 2p spectrum, peaks attributable to -SO<sub>3</sub><sup>x-</sup> (approximately  
28 168.9 eV) and characteristic peaks of the inorganic ZnS component (approximately  
29 162.4 eV) are clearly observable. As the etching depth increases, the ZnS component  
30 gradually intensifies.

In the O 1s spectrum, distinct peaks for C-O-C ( $\approx 533.1$  eV) and C-O/OH ( $\approx 531.6$  eV) are observed, alongside a peak for  $-\text{SO}_4^{2-}$  ( $\approx 532.5$  eV). This indicates SLS molecules participate in forming the SEI film on the zinc electrode surface. In the C 1s spectrum, four characteristic signals are observed: C-C/C-H (approximately 284.8 eV), C-O (approximately 286.5 eV), C=O (approximately 287.8 eV), and a small amount of carbonate (approximately 289.2 eV). The presence of carbonate stems from minor  $\text{CO}_2$  dissolution during sample preparation. The rapid decrease in C-C and C-H signals with increasing depth indicates that organic carbon-based components primarily enrich the outer layer of the interfacial three-dimensional molecular network, while the side adjacent to metallic zinc is dominated by inorganic constituents.

5  
6 Combining the S 2p, O 1s, and C 1s results suggests that under ZS+SLG  
7 electrolyte conditions, a three-dimensional molecular network with "flexible exterior  
8 and rigid interior" forms on the zinc electrode surface: the outer layer, rich in organic  
9 matter, provides high flexibility and strain capacity at the interface, helping mitigate  
10 stress concentration caused by volume changes during zinc deposition/stripping;  
11 while the inner layer is rich in inorganic hard phases such as ZnS and sulfoxides,  
12 acting as a robust barrier against dendrite penetration and corrosion erosion. This  
13 achieves synergistic suppression of zinc dendrite growth and side reactions at the  
14 macroscopic level.

24 To gain insight into how SLG changes the EDL structure of the zinc electrode ,  
25 MD simulation was carried out to investigate the interfacial structure difference  
26 between ZS+SLG and ZS systems (Fig. 2d and Fig. 2e). The normalized density  
27 distribution of interfacial ions (Fig. 2f, 2g), it can be seen that after the introduction of  
28 SLG, SLS molecules seem to mainly exist at positions around 10-20 Å from the zinc  
29 electrode in the distribution function. This result shows some deviation from the  
30 actual spatial distribution because SLS has a large molecular size, and when the  
31 statistical center of mass is calculated, it causes a kind of "extrapolation" position. The  
32 simulation snapshots clearly show that the SLS molecules selectively adsorb and  
33 concentrate around the zinc electrode surface, and some SG molecules also participate  
34 cooperatively to form a continuous three-dimensional molecular network at the  
35 interface. This network is doing two things at once, it slows down how quickly  $\text{Zn}^{2+}$   
36 goes toward the electrode surface, which controls how fast  $\text{Zn}^{2+}$  builds up there, and  
37 also gives  $\text{Zn}^{2+}$  a more even little world to grow and build up along the edge, so the  
38 zinc ions end up building up more regularly on the electrode's surface. The  $\text{Zn}^{2+}$   
39 density peak is more obvious and shifted obviously towards the electrode side  
40 compared with the control electrolyte without SLG. Conversely, the local  
41 concentration of water molecules in the vicinity of the electrode drops considerably.

1 which indicates that the additive can effectively reduce the amount of strong  
2 hydration layer and interfacial free water, thus suppressing the water-related side  
3 reactions, such as HER.  
4  
5

6 And the calculated adsorption energy also agrees with the earlier inference. We  
7 found that the adsorption energy of SLS molecule on Zn(002) crystal plane is about  
8 6.54eV, which is much larger than that of water molecule on the same crystal plane  
9 (about 0.36eV). This means that SLS has a much stronger attraction to the zinc metal  
10 surface than water, it will choose to be at the interface and replace water as the main  
11 "first layer" of the zinc electrode. Furthermore, SLS molecules form a continuous  
12 three-dimensional molecular network on the electrode surface by multiple adsorption  
13 and interaction between molecules. This network successfully avoids bulk water  
14 molecules to come into direct contact with the zinc metal, greatly reducing the  
15 occurrence rate of water-related side reactions like the HER. At the same time, this  
16 molecular network has a screening effect and a channeling effect on "ionic cluster".  
17 These ionic clusters are composed of  $Zn^{2+}$ , water molecules, and SLS. This allows for  
18 the species to traverse this 3D network in a more ordered and uniform manner to  
19 enable synergistic regulation and ordered deposition of  $Zn^{2+}$  at the interface. SG  
20 adsorption energy at the Zn(002) crystal plane is also about 3.00 eV, much larger than  
21 that of water. , This suggests that SG particles are able to synergize the construction of  
22 interfacial layer with SLS, stabilizing the interfacial layer and supporting  $Zn^{2+}$   
23 transport behavior while regulating the solvation structure (Fig. 2h).

44 Following this up, we examined the electron donating capability of SLG additives  
45 and how it affected the zinc metal surface adsorption behaviors by means of  
46 molecular orbital energy levels. As can be seen from Fig. 2i, the introduction of  $-SO_3^{2-}$   
47 group and polyhydroxy structure into the molecules, leads to a significant increase in  
48 the HOMO levels of both SLS and SG compared to  $H_2O$ . It means that it has a  
49 stronger electron-donating tendency towards the atom's surface of metallic zinc,  
50 which makes it easier for the electron density to transfer to the surface of zinc, thus  
51 achieving more stable and firm surface adsorption. The HOMO energy level of the  
52  $Zn^{2+}$ - SG complex is also increased. This suggests that after  $Zn^{2+}$  coordinates with SG,  
53

65

1 its outer layer can increase the "shelter" for H<sub>2</sub>O molecules, thus reducing the  
2 possibility of free water participating in side reactions.  
3

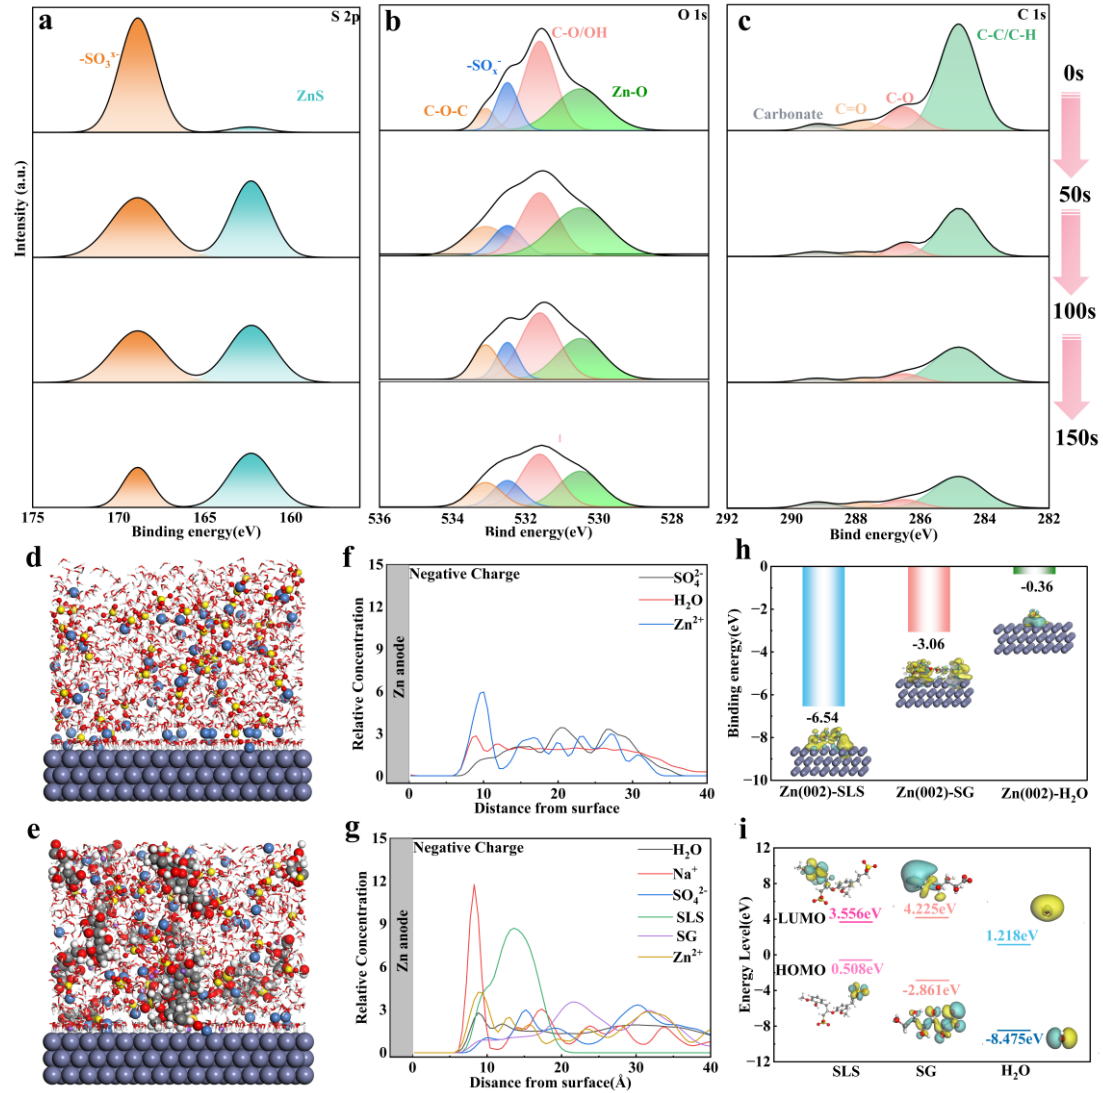

4 Achieving highly stable zinc anodes hinges on regulating zinc ion distribution at  
5 the electrode/electrolyte interface and its deposition/stripping kinetics. Thus, speeding  
6 up Zn<sup>2+</sup> interfacial transport and desolvation will directly affect zinc deposition  
7 density and reversibility. The interfacial compatibility of electrolyte and zinc surface  
8 as well as the electrolyte transport kinetics are two important factors that determine  
9 the long-term stability of zinc anodes. To quantitatively characterize the interfacial  
10 wetting and compatibility after the addition of SLG, we carried out in-situ contact  
11 angle measurement (Fig. 3a). The results showed that the ZS+SLG electrolyte had  
12 better wettability on the zinc surface and a much smaller contact angle. It means that  
13 the electrolyte distributes more evenly on the surface of the electrode, making it easier  
14 to form a uniform electric field and flow of ions, providing the basis for obtaining  
15 uniform zinc deposition. Based on this, we examined the side reactions suppression  
16 capability of SLG, especially for the hydrogen evolution reaction (HER). The linear  
17 sweep voltammogram (LSV) results showed that at the same current density of 10  
18 mA, the potential of ZS + SLG is much higher than that of pure ZS (Fig. 3b). which  
19 shows that under the same driving force, it is more difficult for HER to start in the  
20 SLG-containing electrolyte, and this indicates that the additive can greatly increase  
21 the overpotential of HER, effectively inhibiting the water-related side reaction at the  
22 interface. To make the SLG regulate zinc deposition behavior visible, we also used a  
23 linear potential-stepped CA test (Fig. 3c). In ZS electrolyte without SLG, the zinc  
24 electrode showed a fast current rise over time during constant potential deposition  
25 which suggests preferential 2D growth and then rapid transition to a dendrite  
26 dominated unstable deposition. Conversely, in the ZS+SLG electrolyte, the current  
27 remained steady for the first 30 seconds or so, which is closer to three dimensional  
28 nucleation-diffusion controlled deposition. This proves that SLG can effectively stop  
29 the rapid initial growth of dendrites, making the zinc grow more evenly.  
30

31 To quantitatively quantify the effect of SLG to the interfacial charge-transfer and  
32 desolvation processes. We calculate the E<sub>a</sub> for different electrolyte systems by using

the Arrhenius formula<sup>[39]</sup>. Using the formula (1):

$$1/R_{ct}=A\exp(-E_a/RT) \quad (1)$$

Where  $R_{ct}$  is charge transfer resistance,  $A$  is the pre-exponential factor,  $R$  is the gas constant, and  $T$  is the temperature in Kelvin. All  $R_{ct}$  values were extracted from the EIS curve-fitting data for Zn||Zn symmetrical cell 1s between 20 and 60 °C.

**Fig. 2.** The SEI layer structure and chemical properties of the zinc anode in the ZS+SLG electrolyte system are highlighted by XPS depth profiling, showing prominent distributions of (a) S 2p, (b) C 1s, and (c) O 1s. Chemical composition distribution snapshots near the zinc electrode in (d)ZS and (e)ZS+SLG electrolytes. Normalized density distribution of anions within the EDL in the (f)ZS system and (g) ZS+SLG electrolyte. (h) Ion adsorption energies on the Zn(002) surface. (i) LUMO and HOMO energy levels of SLS, SG, and H<sub>2</sub>O.

From Fig. 3d, 3e and Fig. S1, we can see that  $E_a$  of SLG-containing electrolyte is 22.78 kJ·mol<sup>-1</sup> while  $E_a$  of pure ZnSO<sub>4</sub> electrolyte is 27.93 kJ·mol<sup>-1</sup>. In contrast to each other, SLG greatly diminishes the energy barriers for interfacial charge transfer

1 and desolvation. So that  $Zn^{2+}$  may escape out of the solvated-shell layer, and be  
2 accommodated into the metallic zinc lattice with superior interfacial kinetic property.  
3 Such reduction of energy barriers is consistent with the previously mentioned  
4 restructuring of the SLG's solvation structure and a decrease in the strength of the  
5 strong hydration interaction between free water and  $Zn^{2+}$ .  
6  
7  
8  
9

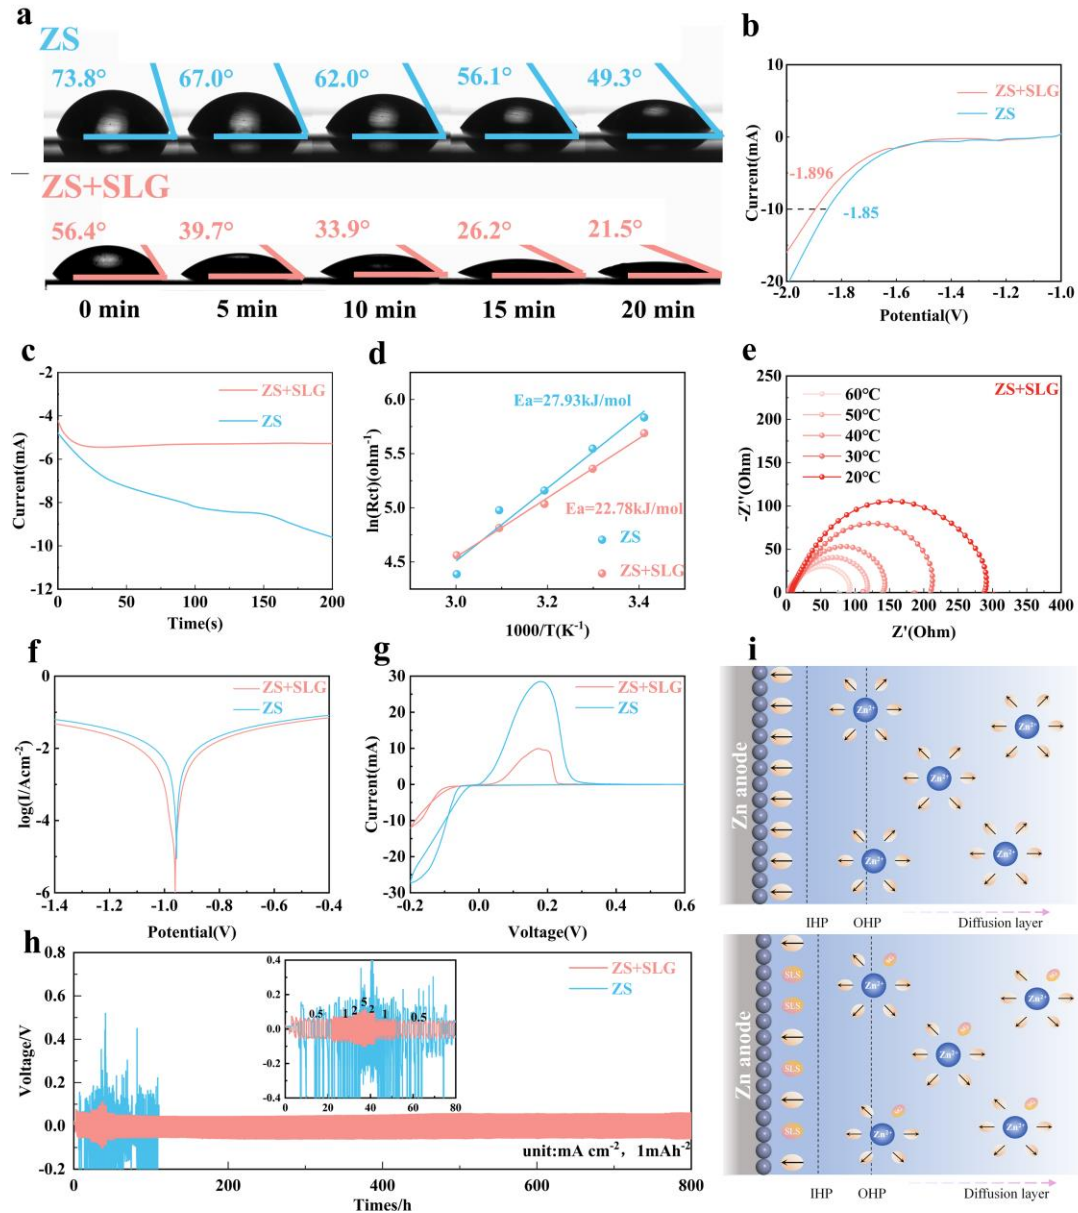

10 To assess the effect of SLG on zinc anode corrosion behaviour, linear polarization  
11 tests were carried out to obtain corrosion current density and potential (Fig. 3f). The  
12 results show that the corrosion current of the zinc anode in the ZS+SLG electrolyte is  
13 only 0.174 mA, which is much less than 1.8 mA in the  $ZnSO_4$  electrolyte. This shows  
14 that the additive greatly reduces the spontaneous corrosion rate of the anode.  
15 Moreover, the corrosion potential of the SLG-containing system was around 0.961 V,  
16 which is more positive than that of the pure  $ZnSO_4$  electrolyte, implying that the  
17 additive could inhibit the anodic corrosion of the zinc substrate. Electrolyte (1.8mA),  
18 this shows that the additive greatly retards the spontaneous corrosion rate of the anode.  
19 Moreover, the corrosion potential in SLG containing system was about 0.961 V which  
20 was higher than that of pure ZS system (0.956 V). This positive potential shift also  
21 suggests that the electrode is in a more "passive" and stable state, indicating the  
22 effective inhibition of SLG on HER and corrosion-related reactions. Similar trends are  
23 seen in nucleation behavior analysis. As can be seen in Fig. 3g, the nucleation  
24 overpotential of zinc in the ZS + SLG electrolyte is around 98 mV, which is far larger  
25 than that of the pure  $ZnSO_4$  electrolyte. The larger the nucleation overpotential is, the  
26 smaller the critical nucleation size will be, and the larger the nucleation density will  
27 be. It can form many small and evenly distributed zinc nuclei, so that the zinc  
28 deposition layer is smoother and denser, rather than a dendritic growth mainly  
29 controlled by a few nuclei.

51 All improvements on the interfacial transport kinetics and deposition behaviour  
52 would finally lead to enhanced full-cell level electrochemical performance. From Fig.  
53 3h we can see that the polarization voltage trend of the  $Zn||Zn$  symmetric cells made  
54 with different electrolytes also shows obvious differences with changing current  
55 densities: under higher current density, the polarization voltage of the symmetric cell

1 using SLG electrolyte is much lower than that of the pure ZnSO<sub>4</sub> system, which  
2 indicates a higher migration rate of Zn<sup>2+</sup> and a lower desolvation barrier. Thus, both  
3 the interfacial resistance and concentration polarization are well reduced. More  
4 importantly, after the same cycling, the cell with SLG electrolyte shows a more stable  
5 polarization curve, which indicates that the cell has better long-term stability than in  
6 the ZnSO<sub>4</sub> system, indicating that Zn<sup>2+</sup> migration rate is faster and the energy barrier  
7 of desolvation is smaller in the former. Interfacial resistance and concentration  
8 polarization have both been successfully reduced. More significantly, after the  
9 variable-rate cycling, the ZS+SLG symmetric cell could still stably operate for more  
10 than 800 h. On the contrary, the ZnSO<sub>4</sub> electrolyte system without impurity showed  
11 extreme voltage fluctuations and even failure in a very short period of time. This  
12 comparison clearly demonstrates that the SLG additive not only optimizes zinc  
13 nucleation and growth behavior during short-term deposition but also significantly  
14 enhances the structural stability and interfacial reversibility of the zinc anode under  
15 long-cycle conditions. This provides strong support for constructing long-life, highly  
16 reliable aqueous zinc-ion battery zinc anodes(Fig. 3i).

31  
32 To investigate the regulatory effect of SLG electrolyte on zinc deposition  
33 behavior, we systematically characterized the surface morphology of cycled zinc  
34 electrodes. First, laser confocal microscopy was used to compare electrode surface  
35 topographies under SLG-free and SLG-containing conditions (Fig. 4a, 4b). In pure ZS  
36 electrolyte, the zinc electrode exhibited high surface roughness (2.257 μm) and  
37 significant height variation (≈ 92 μm), indicating highly non-uniform deposition. On  
38 the contrary, the ZS+SLG electrolyte drastically decreased surface roughness to 0.138  
39 μm, with a height difference of just 10.4 μm, displaying an extremely smooth and  
40 dense surface. This shows that SLG can effectively suppress the localized  
41 uncontrolled growth and large-scale topographical fluctuations. We then disassembled  
42 the electrodes after 50 cycles of the Zn||Zn symmetric cell at a current density of 1  
43 mA cm<sup>-2</sup> and observed the change of surface morphology through SEM. The results  
44 showed that in the pure ZS electrolyte, the surface of the zinc electrode had many  
45 defects, like pitting and cracks due to corrosion and uneven deposition (Fig. 4c),  
46 which indicated serious interfacial side reactions and an imbalanced deposition

process. In contrast, in the SLG electrolyte, zinc deposited as a uniform "cotton-like" coating, with small, uniform grain sizes and very little typical zinc dendritic structure. This indicates that SLG can inhibit the growth of dendrites and promote uniform nucleation and expansion.

**Fig. 3.** (a) In-situ contact angle measurements on zinc electrodes in pure  $\text{ZnSO}_4$  and  $\text{SLG}/\text{ZnSO}_4$  electrolytes. (b) Linear polarization curves describing Zn anode corrosion. (c) CA testing in electrolytes with and without SLG additive, illustrating schematic diagrams of different diffusion behaviors regulated by SLG additive. (d)  $\text{Zn}^{2+}$  activation energies in  $\text{ZnSO}_4$  and  $\text{ZnSO}_4+\text{SLG}$  electrolytes ( $E_a$ ). (e) Variable-temperature impedance of electrolyte in  $\text{ZnSO}_4$  and  $\text{ZnSO}_4+\text{SLG}$ . (f) Tafel curves in 1 M aqueous electrolyte  $\text{Na}_2\text{SO}_4$  with/without SLG additive. (g) CV curves of Zn/Cu cells in electrolyte with/without SLG additive. (h) Rate performance of symmetric cells in electrolyte with/without SLG additive. (i) Schematic of SLG-regulated zinc deposition behavior.

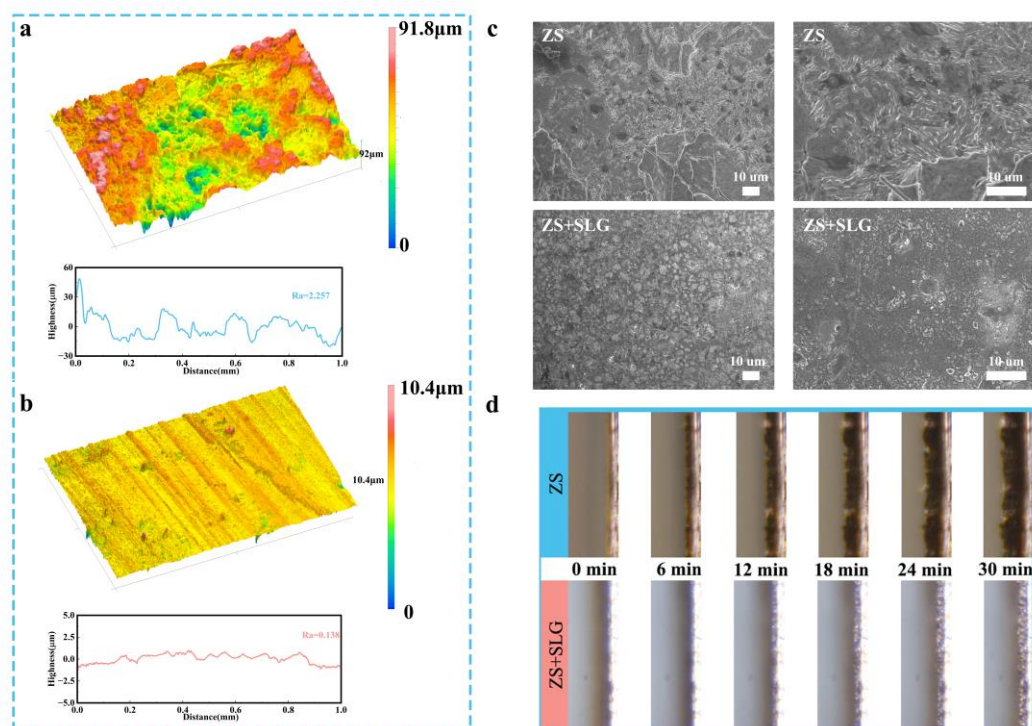

To visualize the deposition process under high current conditions, we created a

1 custom electrolytic cell and examined zinc electrode deposition behavior at 10mA  
2 cm<sup>-2</sup> with in-situ optical microscopy(Fig. 4d). In the electrolyte without SLG, as  
3 deposition occurred, large quantities of coarse, unordered deposits rapidly formed on  
4 the electrode's surface. The deposits were inert insulating by-products and disorderly  
5 dendrites, both of which are prone to causing local short circuits and a reduction in  
6 capacity. On the contrary, for the zinc deposit in the SLG containing electrolyte, a  
7 dense, continuous, and uniform bright region appeared with a smooth deposit surface  
8 and almost no sharp dendritic protrusions. This further demonstrated that SLG could  
9 still keep the deposition very controllable even when the rate was quite high.

10  
11 Furthermore, EDS analysis of the zinc electrode after 50 cycles at 1 mA cm<sup>-2</sup>(Fig.  
12 S4) reveals a homogeneous SEI layer on the electrode surface, consistent with the  
13 organic/inorganic composite three-dimensional interfacial layer previously identified  
14 by XPS.

15  
16 By synergistically introducing sodium lignin sulfonate (SLS) and sodium  
17 gluconate (SG) into the ZnSO<sub>4</sub> electrolyte, we significantly enhanced the electrolyte's  
18 comprehensive performance, thereby substantially improving the interface stability  
19 and cycling reversibility of the zinc anode. First, using a Zn||Zn button-type  
20 symmetric cell as a model, we systematically evaluated the zinc plating/stripping  
21 stability of the SLG-additive electrolyte under varying current density and areal  
22 capacity conditions. As shown in Fig. 5a, under a current density of 1 mA cm<sup>-2</sup> and an  
23 areal capacity of 1 mAh cm<sup>-2</sup>, the symmetric cell with SLG additives operated stably  
24 for approximately 2000 hours, maintaining a steady voltage plateau without  
25 significant fluctuations. In contrast, the electrolyte system containing only SLS  
26 exhibited short-circuit failure after approximately 100 hours, while the system with  
27 only SG additives sustained operation for about 300 hours. The pure ZnSO<sub>4</sub>  
28 electrolyte system, without any additives, failed rapidly after approximately 40 hours.  
29 This stark contrast clearly demonstrates that although a single additive provides some  
30 mitigation for the zinc anode, it remains insufficient to suppress dendrite formation  
31 fundamentally. This stark contrast clearly demonstrates that Only the synergistic  
32 action of SLS and SG can establish a more stable interfacial environment, thereby  
33

32

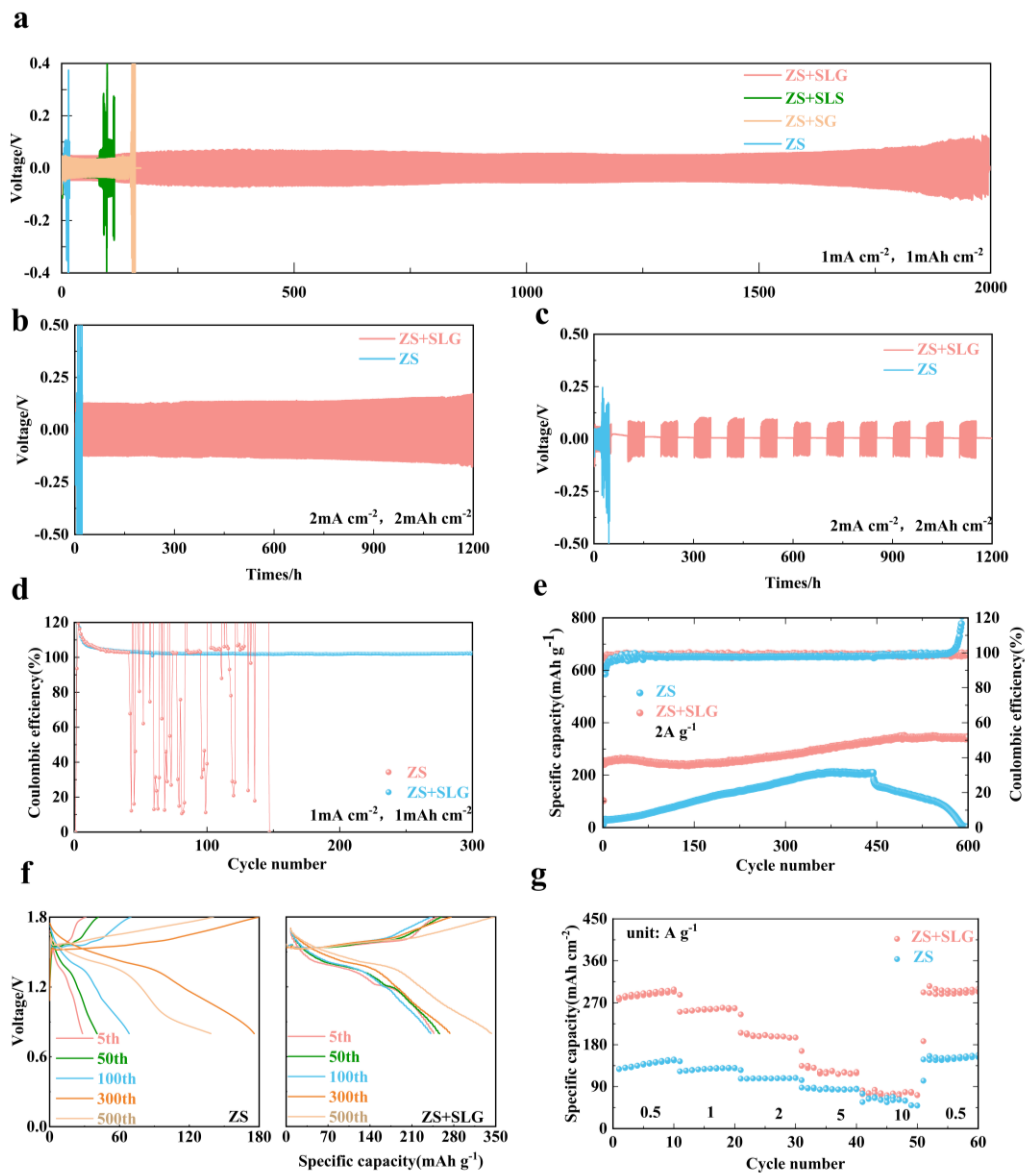

33  
34  
35 Typically, increasing current density and areal capacity intensifies polarization at  
36 the electrode/electrolyte interface, accelerating side reactions and dendrite growth,  
37 thereby significantly shortening battery life. Under more severe conditions of 2 mA  
38  $\text{cm}^{-2}$  and 2 mAh  $\text{cm}^{-2}$ , this trend becomes particularly pronounced. As shown in Fig.  
39 5b, the Zn||Zn symmetric cell in a pure  $\text{ZnSO}_4$  electrolyte system could only maintain  
40 operation for a few hours before rapidly exhibiting voltage instability and  
41 short-circuiting. Under identical conditions, the symmetric cell with SLG additive not  
42 only showed lower polarization voltage but also operated stably for approximately  
43 1200 h. This clearly demonstrates that SLG effectively regulates zinc deposition  
44 morphology, reduces local current concentration and side reaction rates even under  
45 high stress conditions, thereby significantly delaying anode failure. To better simulate  
46 practical applications, we further designed an intermittent cycling condition  
47 alternating between "50 h charge/discharge + 50 h quiescent" (Fig. 5c). Under these  
48  
49

64  
65

1 more severe conditions, which readily induce localized corrosion and dendrite  
2 instability, the pure ZnSO<sub>4</sub> symmetric cell in the pure ZnSO<sub>4</sub> electrolyte system failed  
3 due to short-circuiting after only approximately 30 h of operation. In contrast, the  
4 ZS+SLG system maintained stable operation for over 1200 h, demonstrating that SLG  
5 effectively suppresses dendrite growth and side reactions even during the static phase.  
6 This significantly enhances the long-term durability of the battery under complex  
7 operating conditions.  
8  
9

10 To more intuitively evaluate SLG's effectiveness from the perspective of  
11 plating/stripping reversibility, we further assembled Zn||Cu asymmetric button cells,  
12 using coulombic efficiency (CE) as the core evaluation metric. As shown in Fig. 5d,  
13 the introduction of SLG enables the Zn||Cu battery to maintain a stable voltage  
14 response even at high cycle numbers, with CE sustained above approximately 98%  
15 over 300 cycles( Fig. S5) . In contrast, under identical conditions in a pure ZnSO<sub>4</sub>  
16 electrolyte, the Zn||Cu battery short-circuited and failed after only about 20 cycles due  
17 to dendrite penetration or severe side reactions. Corresponding voltage-time curves  
18 further validate this: in the pure ZnSO<sub>4</sub> system, the voltage rapidly approaches zero  
19 after a short cycle, indicating that the electrode has essentially lost its effective  
20 working interface. In contrast, the polarization voltage in the SLG-containing system  
21 exhibits stable cycling behavior with no significant decay. We compare SLG with  
22 other methods(Fig S6, S7,S8 and Table S2). Combining commonly used CE  
23 evaluation parameters in the literature-including current density, single-cycle areal  
24 capacity, and cumulative plating capacity (CPC),which is evident that the SLG  
25 addition strategy proposed in this work offers significant advantages in reducing side  
26 reactions and enhancing reversibility<sup>[40]</sup>.

48  
49

50 To further prove the feasibility and scalability of SLG additives in practical  
51 full-cells, we prepared MnO<sub>2</sub>@CNT as the cathode and assembled Zn||MnO<sub>2</sub> full cells.  
52 The long term cycling performance was evaluated at 2A g<sup>-1</sup> under ZS+SLG electrolyte  
53 condition. From Fig. 5e we can see that Zn||MnO<sub>2</sub> cell still maintained about  
54 300mAh/g specific capacity after 600 cycles, which had a good retention of capacity.  
55 Meanwhile, the pure Zn||MnO<sub>2</sub> cell retained only around 100 mAh g<sup>-1</sup> of capacity,  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 indicating poor capacity retention. The two full cells retained a capacity around  
 2 300mAhg-1 after 600 cycles, showing good capacity retention. On the other hand, the  
 3 Zn || MnO<sub>2</sub> full cell in a pure ZnSO<sub>4</sub> electrolyte failed quickly after around 400 cycles  
 4 via short-circuiting or serious polarization and its capacity decayed sharply (Fig. 5f).  
 5 Further investigation of the rate performance from 0.2 - 5 A g<sup>-1</sup> (Voltage window: 0.8 -  
 6 1.8 V), it can be observed that the ZS+SLG electrolyte has better discharge  
 7 capacity (Fig. 5g). Combining the results of symmetric cells, asymmetrical cells, and  
 8 whole cells, we find that the SLG additives are able to not only improve the  
 9 plating/stripping reversibility as well as dendrite resistance of zinc anodes, but they  
 10 are able to improve the real-life capacity retention and rate performance as well.

### 3. Conclusion

In summary, we synergistically modulated the deposition of Zn<sup>2+</sup> on the zinc electrode surface using two electrolyte additives-sodium lignin sulfonate and sodium gluconate (SLG). In this system, sodium lignin sulfonate adsorbs onto the zinc electrode to form a three-dimensional molecular network that regulates the flow of zinc ions. This controls the zinc ion deposition rate, promotes uniform zinc ion deposition, significantly enhances the reversibility of Zn<sup>2+</sup> device and simultaneously repels the adsorption of active water, promoting the formation of a water-depleted Helmholtz inner layer. Gluconate ions strongly interact with Zn<sup>2+</sup>, replacing some H<sub>2</sub>O molecules in the solvated structure, effectively suppressing side reactions caused by free water. Based on this, the Zn||ZS+SLG electrolyte in a zinc symmetric cell achieved a 2000-hour cycle life at  $1\text{ mA cm}^{-2}$  and  $1\text{ mAh cm}^{-2}$ . Even at higher current densities and capacity additions, the battery's cycle life was significantly enhanced. Furthermore, the Zn||MnO<sub>2</sub>@CNT battery maintained  $300\text{ mAh cm}^{-1}$ 's capacity after 600 cycles at  $2\text{ A g}^{-1}$ . This study offers a more cost-effective solution. These advancements provide an economically viable and practical solution for next-generation aqueous energy storage systems, thereby improving the commercial viability of aqueous zinc-ion batteries.

Dear editor,

We are glad to submit the manuscript of a paper entitled “**Strategy for Stabilizing Zinc Anodes via Lignosulfonate/Gluconate-Constructed Dehydrated Electric Double Layers and Reconstructed Solvation Sheaths**” to *Journal of Energy Storage* as an article. The manuscript by Minghan Li, Lingge Kong, Shan Yang, Pengtao Wang, Yi Li\*, Kaifeng Yu\* was submitted to you. This article has not been published elsewhere in whole or in part. All authors have read and approved the content, and agree to submit for consideration for publication in the journal. There are no ethical/legal conflicts involved in the article.

Aqueous zinc-ion batteries (AZIBs) are attractive for safe and low-cost energy storage, yet their practical application remains hindered by uncontrolled Zn dendrite growth and parasitic reactions (e.g., hydrogen evolution and corrosion), which deteriorate Coulombic efficiency and cycling stability. Although electrolyte additives have been extensively explored, it is still challenging to concurrently regulate Zn<sup>2+</sup> solvation chemistry and interfacial physicochemical processes using a simple, scalable formulation. In this work, we propose a dual-, enabling synergistic and multidimensional stabilization of the Zn anode. additive ZnSO<sub>4</sub> electrolyte engineering strategy by introducing sodium lignosulfonate (SLS) and sodium gluconate (SG)

Our results reveal distinct yet complementary functions of the two additives. SLS preferentially adsorbs on the Zn metal surface and forms a three-dimensional molecular network that guides Zn nucleation and growth, while repelling interfacial water to construct a dehydrated (water-lean) electric double layer at the metal/electrolyte interface. Meanwhile, SG participants the primary Zn<sup>2+</sup> solvation sheath and displaces reactive water molecules, thereby suppressing hydrogen evolution and corrosion,

refining Zn grains, and promoting uniform Zn deposition. By integrating lignosulfonate-induced interfacial dehydration with gluconate-driven solvation-sheath reconstruction, this straightforward electrolyte design effectively mitigates dendrites and parasitic reactions without increasing manufacturing complexity.

Benefiting from the SLS/SG dual-additive electrolyte, the Zn||Zn symmetric cell achieves stable cycling for 2000 h at  $1 \text{ mA cm}^{-2}$  and  $1 \text{ mAh cm}^{-2}$ , and exhibits markedly extended lifetimes at higher current densities and higher areal capacities. Under more practical conditions, the Zn||MnO<sub>2</sub>@CNT full cell maintains a capacity of approximately  $300 \text{ mAh g}^{-1}$  after 600 cycles at  $2 \text{ A g}^{-1}$ . These results demonstrate that a low-cost and scalable electrolyte regulation strategy can substantially enhance Zn anode interfacial stability, providing a practical pathway toward economically competitive and engineering-feasible aqueous energy storage systems.

We would be grateful if the manuscript could be reviewed and be considered for publication in *Journal of Energy Storage*. If accepted, it will not be published elsewhere in the same form, in English or in any other language, without the written consent of the Publisher.

Yours sincerely

Kaifeng Yu

**Highlights:**

1. The dual-additive system of sodium lignosulfonate and sodium gluconate synergistically regulates zinc deposition and suppresses side reactions.
2. The symmetrical cell, using the modified electrolyte, achieves a 2000-hour cycle life under high current density and high areal capacity.
3. The Zn||MnO<sub>2</sub>@CNT full cell retains a capacity of approximately 300 mAh/g after 600 cycles at 2 A/g.
